Abstract

- 2 Background. Increasing research has found that various methodological steps can
- 3 have an impact on the observed microbial community when using 16S rRNA gene
- 4 surveys. These components include, but are not necessarily limited to, preservation media,
- extraction kit, bead beating time, and primers. Both cycle number and Hifidelity (HiFi) DNA
- 6 polymerase are sometimes overlooked during this conversation of bias considerations.
- 7 Here we critically examine both cycle number and HiFi DNA polymerase for biases that
- may influence downstream diversity measures of 16S rRNA gene surveys.
- Methods. DNA from Fecal samples (n = 4) were extracted using a single PowerMag DNA extraction kit with a 10 minute bead beating step and amplified at 15x, 20x, 25x, 30x, and 35x using Accuprime, Kappa, Phusion, Platinum, or Q5 HiFi DNA polymerase. Mock communities (technical replicates n = 4) consisting of the whole genome of 8 different bacteria were also amplified using the same approach. The number of OTUs (Operational Taxonomic Units) was first examined for both fecal samples and mock communites. Next, Bray-Curtis index, the error rate, sequence error prevalence, and chimera prevalence, and the chimera prevalence correlation with number of OTUs was assessed for either cycle number or HiFi DNA polymerase dependent differences.
- Results. At 35 cycles there were significant differences between HiFi DNA polymerase for fecal samples (P-value < 0.0001). These HiFi dependent differences in the number of OTUs could be identified as early as 20 cycles in the mock communities (P-value = 0.002). Chimera prevalence varied by HiFi DNA polymerase and these differences were still observed after chimera removal using VSEARCH. Additionally, the chimera prevalence had a strong positive correlation with the number of OTUs observed in a sample and was also not changed by chimera removal with VSEARCH.
- Conclusions. Due to the impact of HiFi DNA polymerase on the number of OTUs, common

- ²⁶ diversity metrics that incorporate this value could give artificially inflated numbers due
- 27 to higher undetected chimeras. So, when designing 16S rRNA gene survey studies it is
- 28 important to consider both the cycle number and the type of HiFi DNA polymerase that will
- be used since it can increase or decrease the number of OTUS that are observed.

30 Introduction

Over recent years there has been an increasing focus on standardizing methodological approaches in microbiota research (Kim et al., 2017; Hugerth & Andersson, 2017). In particular, a lot of the attention of this standardization push has been invested in 33 investigating ways that 16S rRNA gene surveys can be made more replicatable (Lauber 34 et al., 2010; Salter et al., 2014; Song et al., 2016; Gohl et al., 2016). Although 16S 35 rRNA gene sequencing has been much maligned for introduced bias, many of these same considerations also affect metagenomic sequencing (Nayfach & Pollard, 2016; Costea 37 et al., 2017). Between the two approaches similar bias considerations include, but are 38 not limited to, preservation media, storage conditions, DNA extraction kit, PCR, and sequence library preparation. Thus what is identified as a source of bias in 16S rRNA gene sequencing for these overlapping considerations will also influence metagenomic 41 sequencing results.

The most commonly studied biases are by far the skews introduced to the data via preservation media used, storage conditions, and DNA extraction kits chosen. The study of these specific biases has become so large, aggregating them all together has become 45 a difficult task and some researchers provide resources to actively track new findings (e.g. Microbiome Digest - https://microbiomedigest.com/microbiome-papers-collection/ 47 microbiome-techniques/sample-storage/). Within the literature DNA extraction kits have consistently been shown to add bias to downstream analysis (Salter et al., 2014; Costea et al., 2017). However, the current literature on preservation media and storage conditions 50 has been more mixed, with some studies showing biases while others do not (Lauber et 51 al., 2010; Dominianni et al., 2014; Sinha et al., 2015; Song et al., 2016; Luo et al., 2016; 52 Bassis et al., 2017). Although these are important sources of bias they are not the only sources that should be critically examined. The type of DNA polymerase chosen could have a wide ranging affect on downstream results due to error rates and chimeras that

may not be easily resolved using bioinformatic approaches.

A recent study in *Nature Biotechnology* showed that there were clear differences between 57 normal and high fidelity (HiFi) DNA polymerase and that you could reduce error and 58 chimera generation by optimizing the PCR protocol (Gohl et al., 2016). Another important 59 component of this study was that differences, based on DNA polymerase, in the number of OTUs generated were not easily removed using the authors chosen bioinformatic pipeline 61 (Gohl et al., 2016). Although it is probably not surprising that normal DNA polymerase 62 performed worse than HiFi DNA polymerase, it is natural to extend this line of inquiry and ask whether different HiFi DNA polymerase contribute different biases to downstream sequencing results. There is some reason to think that this may be the case since many of these HiFi DNA polymerase come from different families and may intrinsically have different error rates that cannot be completely removed with modifications (Ishino & Ishino, 2014). In this study we critically examine if any of five different HiFi DNA polymerase introduce noticeable biases into 16S rRNA gene surveys, if this is a cycle dependent phenomenon, and whether they can be removed using a standard bioinformatic pipeline.

We amplified the 16S rRNA gene in both fecal and mock community samples using either
Accuprime, Kappa, Q5, Phusion, or Platinum HiFi DNA polymerase. First, we tested if we
could identify differences in the number of OTUs between the differen HiFi DNA polymerase
for both the fecal and mock samples. Next, since there were differences based on HiFi DNA
polymerase, we examined if a community measure such as the Bray-Curtis index would be
affected. After assessing these community measures we then examined if the different
HiFi DNA polymerase had different per base error rates as well as chimera prevalence.
Finally, since differences in chimera prevalence, based on HiFi DNA polymerase, could not
be completely removed using bioinformatic approaches we tested whether the chimera
prevalence correlated well with total number of observed OTUs.

Materials & Methods

Human and Mock Samples: A single fecal sample was obtained from 4 individuals who were part of the Enterics Research Investigational Network (ERIN) and the processing and storage of these samples have been published previously (Seekatz et al., 2016). 84 Clinical data and other types of meta data were not utilized or accessed for this study. All 85 samples were extracted using the MOBIOTM PowerMag Microbiome RNA/DNA extraction kit (now Qiagen, MD, USA). The ZymoBIOMICSTM Microbial Community DNA Standard 87 (Zymo, CA, USA) was used in this study and is made up of *Pseudomonas aeruginosa*, 88 Escherichia coli, Salmonella enterica, Lactobacillus fermentum, Enterococcus faecalis, 89 Staphylococcus aureus, Listeria monocytogenes, and Bacillus subtilis at equal genomic DNA (http://www.zymoresearch.com/microbiomics/microbial-standards/ 91 zymobiomics-microbial-community-standards).

PCR Protocol: The five different high fidelity (HiFi) Taq DNA polymerase that were tested were AccuPrimeTM (ThermoFisher, MA, USA), KAPA HIFI (Roche, IN, USA), Phusion (ThermoFisher, MA, USA), Platinum (ThermoFisher, MA, USA), and Q5 (New England Biolabs, MA, USA). The PCR cycle conditions for Platinum and Accuprime followed a previously published protocol (Kozich et al., 2013) (https://github.com/SchlossLab/MiSeq_ WetLab_SOP/blob/master/MiSeq_WetLab_SOP_v4.md). If the HiFi Taq had a specific activation time that was different then 2 minutes, the specified activation was used instead. For Kappa and Q5 the protocol previously published by Gohl and colleagues was used (Gohl et al., 2016). For Phusion the company defined conditions were used but the same extension time as that used for Accuprime and Platinum was used.

The 30 cycle default was used but the cycle conditions started at 15 and increased by 5 up to 35 cycles and was used for both fecal and mock samples. The fecal PCR consisted of all 4 samples at 15, 20, 25, 30, and 35 cycles for each Tag (total samples = 100). Although, the

mock communities also had 4 replicates used for 15, 20, 25, and 35 cycles, 10 replicates
were used for 30 cycles for all Taq (total samples = 130). For all the mock community
samples there was not enough PCR product at 15 cycles for adequate sequencing.

Sequence Processing: The mothur software program was utilized for all sequence processing steps (Schloss et al., 2009). The protocol followed was similar to what has been previously published (Kozich et al., 2013) (https://www.mothur.org/wiki/MiSeq_SOP). Two major differences from the stated protocol were the use of VSEARCH instead of UCHIME for chimera detection and the use of the OptiClust algorithmn instead of average neighbor for Operational Taxonomic Unit (OTU) generation at 97% similarity (Edgar et al., 2011; Rognes et al., 2016; Westcott & Schloss, 2017). Sequence error was determined using the seq.error command on mock samples after chimera removal and classification to the RDP to remove non-bacterial sequences (Schloss et al., 2009; Cole et al., 2013; Rognes et al., 2016).

Statistical Analysis: All analysis was done with the R (v 3.4.3) software package (R Core 119 Team, 2017). Data tranformation and graphing was completed using the tidyverse package 120 (v 1.2.1) and colors selected using the viridis package (v 0.4.1) (Garnier, 2017; Wickham, 121 2017). Differences in the total number of OTUs were analyzed using an ANOVA with a 122 tukey post-hoc test. For the fecal samples the data was normalized to each individual by cycle number, to account for the biological variation between different people. Bray-Curtis 124 matrices were generated using mothur after 100 sub-samplings at 1000, 5000, 10000, and 15000. The distance matrix data was analyzed using PERMANOVA with the vegan package (v 2.4.5) (Oksanen et al., 2017) and kruskal-wallis tests within R. For both error and chimera analysis, samples were tested using Kruskal-Wallis with a Dunns post-hoc 128 test. Where applicable correction for multiple comparison utilized the Benjamini-Hochberg 129 method (Benjamini & Hochberg, 1995). 130

Analysis Workflow: The total number of OTUs after sub-sampling was analyzed for both

the fecal and mock community samples. Cycle dependent affects on Bray-Curits indicies were next assessed for the fecal samples looking at both overall cycle differences and 133 within individual differences for the previous cycle (e.g. 20 versus 25, 25 versus 30, etc.). 134 Based on these observations we wanted to next analyze potential reasons as to why some 135 of these differences may have occured. First, analysis of general sequence error rate, 136 number of sequences with an error, and base substitution were assessed in the mock 137 community for each DNA polymerase. After assessing these errors, the total number of 138 chimeras was determined after sequence processing. For the community based measures, 139 the fecal samples were analyzed at 4 different sub-sampling levels, 1000, 5000, 10000, 140 and 15000 while the mock community samples were analysed at 3 levels, 1000, 5000, 141 10000. 142

Reproducible Methods: The code and analysis can be found here https://github.com/
SchlossLab/Sze_PCRSeqEffects_XXXX_2017. The raw sequences can be found in the
SRA at the following accesssion number need to upload still.

Results

The Number of OTUs is Dependent on HiFi DNA Polymerase Used: normalization by individual, for each cycle number, we observed that for fecal 148 samples the number of OTUs identified was dependent upon the HiFi DNA polymerase 149 used and this difference increased as the depth of sub-sampling increased [Figure 1]. 150 Lower cycle numbers (15-20) resulted in less differences between HiFI DNA polymerase 151 while cycle numbers of 25, 30, and 35 had larger clearer defined differences [Figure 1]. 152 Only 35 cycles had HiFi DNA polymerase differences that were significantly different at 153 all sub-sampling levels (P-value < 0.0001) [Table S1]. At sub-sampling depth of 5000 or 154 higher 25 and 30 cycles had HiFi DNA polymerase differences (P-value < 0.05) [Table 155 S1]. Using a Tukey post-hoc test only at 35 cycles were significant differences found 156 to be mainly driven by Platinum being different than all other DNA polymerases across 157 sub-sampling depth (P-value < 0.05) [Table S2]. 158

This HiFi DNA polymerase dependent difference in the number of OTUs was also observed 159 in the mock community samples with the same DNA polymerases being high (Platinum) and 160 low (Accuprime) respectively [Figure 2 & Table S3]. Conversely, differences between HiFi 161 DNA polymerase were observed as early as 20 cycles and a sub-sampling depth of 1000 162 sequences (P-value = 0.002) [Table S3]. Using a Tukey post-hoc test differences between 163 Platinum and the other HiFi DNA polymerases was the major driver of the differences 164 seen at different cycle numbers and sub-sampling depths [Table S4]. Both fecal and mock 165 samples consistently showed that across sub-sampling depth and cycle number the lowest 166 number of OTUs identified was from AccuprimeTM while the highest was from Platinum for 167 both fecal and mock samples [Figure 1 & 2]. 168

Minimal Bray-Curtis Differences are Detected by Cycle Number: Overall, there was very little difference between each respective 5-cycle increment (e.g. 15x vs 20x) for both

fecal and mock samples and this was consistent across the different sub-samplings used [Figure 3]. Two exceptions to the low differences between 5-cycle increments can be found. The first, that there seems to be large differences for fecal samples between 20x vs. 25x that is robust against sub-sampling depth [Figure 3A-B]. Second, for the mocks, where data is available, there appears to be a similar large difference detected between 20x and 25x [Figure 3D]. Regardless, by the time PCR cycles reach 25x there does not seem to be large differences in the community between the same sample [Figure 3].

Using PERMANOVA to test whether there were any differences within HiFi DNA polymerase 178 groups based on cycle number, only Phusion had cycle dependent differences at 1000 and 5000 sub-sampling depth (P-value = 0.03 and 0.01, respectively). Interestingly, Phusion was one of only two DNA polymerase that managed to have samples for the 181 1000 sub-sampling depth at 15 cycles. Next, we assessed whether there were any major differences between 5 cycle increments within each sample. We found that there 183 was no detectable difference in Bray-Curits index when comparing to the previous 5 cycle 184 increment (P-value > 0.05). However, Phusion at 1000 sub-sampling depth had a P-value = 185 0.02 before multiple comparison correction. It should be noted that at higher sub-sampling 186 depths these differences in Bray-Curits indicies disappear for both differences in cycle 187 number and within 5 cycle increments within an individual. 188

Sequence Error is Dependent on both HiFi DNA Polymerase and Cycle Number

Used: Differences by HiFi DNA polymerase in the median average per base error varied
without a clear pattern across sub-sampling depth [Table S5]. Generally, the highest values
were for the Kappa HiFI DNA polymerase and the pre-cluster step and chimera removal by
VSEARCH had little effect on this rate [Figure 4]. Generally, there were small differences
between the various HiFi DNA polymerase at lower cycle numbers and larger differences
at higher cycle number with Platinum having large differences between all other HiFi DNA
polymerase [Figure 4B-C and Table S6].

The total segeunces with at least one error had multiple differences at different cycle numbers and was mostly alleviated by the use of the pre.cluster step [Figure S1]. Major differences before this pre.cluster step were driven by large differences in AccuprimeTM and Platinum versus the other HiFi DNA polymerase tested [Figure S1 & Table S7 & S8]. 200 Although AccuprimeTM had the lowest per base error rate it had the largest number of 201 sequences with at least one error, regardless of cycle number or sub-sampling depth 202 [Figure S1]. However, this increased number of sequences with an error can be drastically 203 lowered with existing bioinformatic approaches [Figure S1]. Investigation of whether there 204 were HiFi DNA polymerase dependent effects on base substitution found that there were 205 generally no biases in the types of substitution made [Figure S2]. 206

Chimeric Sequences Correlate with OTUs and are HiFi DNA Polymerase Dependent:

208

211

212

213

214

215

216

After chimera removal using VSEARCH and removal of sequences that did not classify as bacteria we assessed the percentage of sequences that were still chimeric within our mock community. At all levels of sub-sampling and cycle number there were significant differences between the HiFi DNA polymerase used (P-value < 0.05) [Table S9]. Using a Dunn's post-hoc test the vast majority of these differences were driven by Platinum being different then all other HiFi DNA polymerase across cycle number and sub-sampling depth [Table S10]. Generally, across sub-sampling depth and cycle number AccuprimeTM had the lowest chimera prevalence of all the HiFi DNA Polymerase regardless of whether pre-cluster or VSEARCH had been used [Figure 5].

For all DNA polymerase, a positive correlation was observed between chimeric sequences and number of OTUs, with this correlation being strongest for Accuprime, Platinum and Phusion HiFi DNA Polymerase [Figure 6]. In general, the R² value between the number of OTUs and chimeric sequences did not change from the use of pre.cluster and VSEARCH [Figure 6]. Taken together this data suggests that a strong correlation exists between the number of OTUs and the prevalence of chimeric sequences. Additionally, Kappa had the

- highest per base error rate and the lowest correlations between the number of OTUs and
- chimeric sequences across sub-sampling depth [Figure 4 & 6].

Discussion

Our observations build upon previous studies (Gohl et al., 2016) by showing that even different HiFi DNA polymerase have significant differences in the number of OTUs and that the changes to total OTUs correlate with chimeras not removed after sequence processing [Figure 1-2 & 5]. This is important since many diversity metrics rely on the total number of 229 OTUs as part of their calculations and changes to the total number of OTUs could drastically 230 change the results, as well as the findings. Although the attention has mostly been focused 231 on standardizing and improving collection and extraction methods (Salter et al., 2014) our 232 observations show that independent of this consideration HiFi DNA polymerase can have 233 a noticeable affect on the OTUs generated that can be found across sub-sampling depth 234 and PCR cycle number [Figure 2-4]. These differences were observed in high biomass 235 samples, where biases introduced by such components like kit contamination may have 236 less of an effect, suggesting that these differences may be exacerbated in low biomass 237 samples. 238

Although we did not observe strong differences, based on cycle number, using the 239 Bray-Curtis index the data suggests that there may be differences between 15 cycles and 240 higher cycle numbers, such as 30x, that are commonly used. Additionally, there was no 241 difference within individuals between corresponding 5 cycle increments (e.g. 15 to 20, 20 242 to 25, etc.). Conversely, this may be due to low power and on observation there does seem 243 to be a trend that 20x and 25x communities are very different from each other [Figure 3]. 244 This finding, in conjunction with the PERMANOVA results, suggest that cycle number can 245 change bacterial community calculations but that these differences are minimal once 25 246 cylces are reached. Increasing the sub-sampling depth, for some DNA polymerase, may 247 reduce some of these observed community differences at lower cycle numbers. 248

49 Increasing the cycle number also exacerbated chimera prevalence differences between

the different HiFi DNA polymerases [Figure 5]. The chimera prevalence was strongly correlated with the number of OTUs and this value is relied upon heavily for many different downstream community metric calculations. However, Bray-Curtis analysis with PERMANOVA showed few differences based on DNA polymerase. Since it is possible that many of the increased number of OTUs, generated as cycle number increases, are not highly abundant allowing the Bray-Curtis index to be able to successfully downweight these respective OTUs (Minchin, 1987). So, choice of downstream diversity metric could be an important consideration in helping to mitigate these observed changes due to high chimera prevalence in HiFi DNA polymerase.

Our observations suggest that there are clear HiFi dependent differences in both per base 259 error rate and chimeras that cannot be removed using bioinformatic approaches [Figure 4 260 & 5]. Although it may be a natural assumption that the variation may be due to the DNA 26 polymerase family, the highest chimera rate, from Platinum, was a family A polymerase 262 while the lowest, from Accuprime, was also an A polymerase (Ishino & Ishino, 2014). In 263 fact, from the material safety data sheet (MSDS), it is not clear what the difference between 264 the two different mixes really is. Both Accuprime and Platinum contain a recombinant *Taq* 265 DNA polymerase, a *Pycrococcus* spp GB-D polymerase and a platinum *Tag* antibody. It is 266 possible that differences in how the recombinant Tag was generated could be the main 267 reason for the differences in chimera rate since all samples were also sequenced at the 268 same time as well as amplified using the same machine. 269

70 Conclusion

Our findings show that measures that rely on number of OTUs will be specific for a particular study and may not be easily generalized to other studies that may be studying a similar area. Care should be taken when choosing a HiFi DNA polymerase for 16S rRNA gene surveys since intrinsic differences can change the number of OTUs observed as well as potentially influence diversity based metrics that do not down weight rare observations.

- Figure 1: Normalized Fecal Number of OTUs. A) Sub-sampled to 1000 reads. B)
 Sub-sampled to 5000 reads. C) Sub-sampled to 10000 reads. D) Sub-sampled to 15000
 reads. The dotted line represents no change from the mean number of OTUs within that
 specific individual.
- Figure 2: Mock Sample Variability in Number of OTUs based on HiFi DNA
 Polymerase. A) Sub-sampled to 1000 reads. B) Sub-sampled to 5000 reads. C)
 Sub-sampled to 10000 reads. The dotted line represents the number of OTUs genereated
 when the mock reference sequences are run through the pipeline.
- Figure 3: Five Cycle Interval Community Differences. A) Fecal samples sub-sampled to 1000 reads. B) Fecal samples sub-sampled to 5000 reads. C) Fecal samples sub-sampled to 10000 reads. D) Mock samples sub-sampled to 1000 reads. E) Mock samples sub-sampled to 5000 reads. F) Mock samples sub-sampled to 10000 reads. The solid black lines represent the median Bray-Curtis index difference within sample for each 5 cycle interval.
- Figure 4: HiFi DNA Polymerase Per Base Error Rate in Mock Samples. A) Error rate before the merger of sequences with pre.cluster and the removal of chimeras with VSEARCH. B) Error rate before the removal of chimeras with VSEARCH. C) Full pipeline.

 The error bars represent the 75% interquartile range of the median.
- Figure 5: HiFi DNA Polymerase Chimera Prevalence in Mock Samples. A) Chimera sequence percentage before the merger of sequences with pre.cluster and the removal of chimeras with VSEARCH. B) Chimera sequence percentage before the removal of chimeras with VSEARCH. C) Full pipeline. The error bars represent the 75% interquartile range of the median.
- Figure 6: The Correlation between Number of OTUs and Chimeras. A) Correlation before the merger of sequences with pre-cluster and the removal of chimeras with

VSEARCH. B) Correlation before the removal of chimeras with VSEARCH. C) Correlation with full pipeline.

Figure S1: HiFi DNA Polymerase Sequence Error Prevalence in Mock Samples. A)

Sequence error prevalence before the merger of sequences with pre.cluster and the
removal of chimeras with VSEARCH. B) Sequence error prevalence before the removal of
chimeras with VSEARCH. C) Full pipeline. The error bars represent the 75% interquartile
range of the median.

Figure S2: HiFi DNA Polymerase Nucleotide Substitutions in Mock Samples.
