Abstract

Background. A typical 16S rRNA gene sequencing workflow can be divided into preservation, extraction, amplification, and sequencing steps. At each of these stages error can be introduced that will change the underlying bacterial community composition results. In this study, we focus on the amplification step's contribution to this overall error. To accomplish this we assessed 16S rRNA gene sequencing results in human fecal and mock community samples after using different high fidelity (HiFi) DNA polymerases and number of amplification cycles.

Methods. We extracted DNA from fecal samples (n=4) using a PowerMag DNA extraction kit with a 10 minute bead beating step and amplified at 15, 20, 25, 30, and 35 cycles using Accuprime, Kappa, Phusion, Platinum, or Q5 HiFi DNA polymerase. Amplification of mock communities (technical replicates n=4) consisting of previously isolated whole genomes of 8 different bacteria used the same approach. We first assessed GC dependent differences, error rate, sequence error prevalence, chimera prevalence, and correlation between chimera prevalence and number of Operational Taxonomic Units (OTUs) by polymerase and number of cycles. Next, differences in the number of OTUs was examined based on the polymerase and number of cycles used. Additionally, differences in the bacterial community composition by the Bray-Curtis index also was assessed based on polymerase and number of cycles. Based on these findings individual taxa differences based on polymerase and number of cycles was investigated. Finally, Random Forest models were created to test whether the bacterial community was better at classifying polymerases, number of cycles, or individual donor. We also assessed whether the most important taxa in the polymerase and number of cycle Random Forest models were also important in the model for individual donors.

Results. Predictably, we found noticeable differences in relative abundance based on high and low GC content (P-value $\leqslant$ 0.04). Chimera prevalence in mock communities varied by polymerase with differences being most notable at 35 cycles (Kappa = 5.71% (median) versus Platinum = 26.62%) and this variation persisted after chimera removal using VSEARCH. We also observed positive correlations between chimera prevalence and the number of OTUs with Platinum having the highest (R^2 = 0.974) and Kappa having the worst (R^2 = 0.478). When analyzing mock community samples the variation in the number of OTUs detected by the polymerases was observable as early as 20

cycles (P-value = 0.002). There also was a large range in the number of OTUs amplified by the polymerases at 35 cycles (Accuprime = 15 - 20 versus Phusion = 14 - 73). When analyzing fecal samples we observed similar differences in the number of OTUs. However, the median number of OTUs only varied by HiFi DNA polymerase used at 35 cycles and not at 20 cycles like the mock community (P-value < 0.0001). Random Forest models were most successful at classifying individual donor samples rather than polymerase or number of cycles used (P-value ≤ 5.49e-07). Additionally, the most important OTUs in the polymerase and number of cycle models were not the most important in the individual donor sample model.

Conclusions. Although there are 16S rRNA gene sequencing differences based on polymerase and number of cycles used, they are small with respect to the biological differences between fecal bacterial communities within individuals. Collectively, these results provide evidence that a real biological difference between groups, based on 16S rRNA gene sequencing of fecal samples, should be detectable regardless of polymerase and number of cycles used.

Introduction

The bacterial community is reported to vary between case and control for a number of diseases (Turnbaugh et al., 2008; Sze et al., 2015; Baxter et al., 2016; Bonfili et al., 2017). However, for diseases like obesity, the taxa identified have varied widely depending on the study (Turnbaugh et al., 2008; Zupancic et al., 2012). Some of this variation could be due to error introduced during the 16S rRNA gene sequencing workflow. A typical 16S rRNA gene sequencing workflow can be divided into preservation, extraction, PCR, and sequencing steps. The preservation and extraction stages of the 16S rRNA gene sequencing workflow have been the most extensively studied (Salter et al., 2014; Song et al., 2016; Bassis et al., 2017; Kim et al., 2017). For preservation and extraction stages of the workflow, it has been consistently found that there are errors in the observed bacterial community composition based on the kits used, but that these differences are smaller than the overall biological difference measured between samples with different kits (Song et al., 2016; Bassis et al., 2017). Since these studies use the same PCR approach while varying preservation or extraction method, the contribution of PCR error to this overall workflow is not as well characterized.

There is a large body of literature that shows there are errors due to primer and number of cycles chosen for the PCR stage of 16S rRNA gene sequencing (Eckert & Kunkel, 1991; Burkardt, 2000). Primers have variable region dependent binding affinities which causes an inability to detect specific bacteria (e.g. V1-V3 does not detect *Haemophilus influenzae* and V3-V5 does not detect *Propionibacterium acnes*) (Sze et al., 2015 (Table S4); Meisel et al., 2016). Another source of error is the selective amplification of AT-rich over GC-rich sequences which exaggerate the difference between 16S rRNA genes higher in AT versus those higher in GC content (Polz & Cavanaugh, 1998). Many of these sources of error are made worse as the number of cycles increases (Wang & Wang, 1996; Haas et al., 2011; Kebschull & Zador, 2015). For example, both amplification error and non-specific amplification (e.g. incorrect amplicon size products) also can increase as the number of cycles increases. This will increase the number of Operational Taxonomic Units (OTUs) observed and drastically change the values obtained from commonly used diversity measures (Acinas et al., 2005; Santos et al., 2016). Additionally, as the number of cycles increases more chimeras can form from an aborted extension step that causes a priming error and subsequent secondary extension

4

70 (Haas et al., 2011). These chimeras will artificially increase community diversity by increasing the

71 number of OTUs that are observed (Haas et al., 2011). In addition to these sources of errors, there

72 also are multiple families of DNA polymerases that have their own error rate and proof reading

73 capacity (Ishino & Ishino, 2014). For simplicity, the use of the term 'error' within the context of this

74 study will be used as a broad term for changes in the downstream sequencing results due to the

75 amplification step (e.g. higher GC content genomes, base substitutions, chimeras, changes from

76 the expected relative abundance, etc.).

77 Interestingly, the influence different DNA polymerases can have on the observed 16S rRNA gene

78 sequencing results have not been well studied like some of the other sources of PCR-based error.

79 A recent study found differences in the number of OTUS and chimeras between normal and high

80 fidelity DNA polymerases (Gohl et al., 2016). The authors of this study could reduce the difference

81 between two polymerases by optimizing the annealing and extension steps within the PCR protocol

82 (Gohl et al., 2016). Yet, within this study there was no comparison made between different high

83 fidelity DNA polymerases on the same samples. The authors instead focused their efforts on testing

84 specific types of amplification methods. Additionally, the fecal samples that were analyzed, as a

85 model of a more complex community, may overestimate the biological variation in human samples

86 due to the comparison of captive versus semi-captive red-shanked doucs. Due to these gaps, it

87 makes sense to extend the previous line of inquiry to include a more detailed examination of two

88 specific areas. First, whether differences in PCR error are detected based on number of cycles

89 used and high fidelity polymerases. Second, whether these differences in error are enough to

90 obscure smaller biological signals than what has been previously reported (Gohl et al., 2016).

91 This study will investigate whether there are error differences that are dependent on high fidelity DNA

92 polymerases and whether these differences obscure the biological variation in the fecal bacterial

93 communities between individuals. We accomplish this by first examining GC-based amplification

94 error, sequence error (e.g. substitutions), chimera prevalence, the number of OTUs, Bray-Curtis

95 index, and OTU-based differences at varying number of cycles in five different high fidelity DNA

96 polymerases in mock communities. In addition to these metrics we also created Random Forest

97 models of the mock community to assess how successful classification based on 16S rRNA gene

98 sequencing of number of cycles and type of polymerase could be. We then assessed if similar

differences in the number of OTUs, Bray-Curtis index, and OTUs could be detected in human fecal samples. Additionally, we also created Random Forest models to assess how successful they could be at classifying fecal samples by number of cycles, polymerase used, or individual. Collectively, our observations suggest that although detectable differences occur based on number of cycles or high fidelity DNA polymerase used, they are smaller than the biological differences between individuals.

Results

Error differences due to number of cycles or polymerase used are detectable in mock communities. There was a significant difference in relative abundance between high/low GC content based on either the V4 16S rRNA gene region or the whole genome [Figure 1 & Table S1]. However, using only the GC content of the V4 region resulted in less differences than when using the whole genome [Table S1]. The differences between high and low GC content groups were significant as early as 20 cycles in all polymerases except Q5 [Table S1]. The highest (*Staphylococcus*) and lowest (*Pseudomonas*) GC content bacteria were the most divergent from the expected relative abundance of 0.12 [Figure 1]. These observations suggest that the high fidelity DNA polymerases tested do not prevent GC-based amplification error.

The median error rate varied by polymerase, with Kappa having the highest error rate of all the polymerases across the number of cycles [Figure 2A & Table S2]. Thus, the majority of the differences observed across the number of cycles was between Kappa and other polymerases [Figure 2A & Table S3]. The total sequences that contained at least one error was also polymerase dependent, with the majority of differences being between Kappa or Accuprime and the other polymerases [Table S2 & S3]. These differences in error rates were not due to polymerase dependent differences in base substitution rate [Figure S1]. Collectively, the results suggest that sequence error is dependent on polymerase, persists across the number of cycles used, and are not due to any bias towards a specific type of base substitution.

We next examined whether chimeras also were dependent on polymerase and whether this could affect the total number of OTUs. We observed significant differences in the chimera prevalence based on polymerase across the number of cycles used (P-value < 0.05) [Table S2]. Differences in chimera prevalence between Platinum and all other polymerases accounted for the majority of these differences [Table S3]. Accuprime[TM] had the lowest chimera prevalence of all polymerases regardless of whether chimera removal with VSEARCH was used [Figure 2B & 2C]. The number of cycles used clearly increased chimera prevalence for all polymerases but the rate of increase differed [Figure 2B & 2C]. There was also a plateau in the total percent of chimeras that were removed that was similar for all polymerases [Figure 2D]. Additionally, a positive correlation was

133 observed between chimeric sequences and the number of OTUs for all polymerases [Figure 2E].

134 This positive correlation was strongest for Accuprime^{TM}, Platinum, and Phusion [Figure 2E]. This

135 data suggests that chimera prevalence depends on polymerase, is made worse by increasing the

136 number of cycles, and confirms previous reports that the number of OTUs is dependent on the

137 prevalence of these chimeric sequences.

138 ***Bacterial community composition differences based on number of cycles or polymerase***

139 ***used are less obvious in mock community samples.*** Due to the close relationship between

140 chimera prevalence and the number of OTUs, we also observed a polymerase dependent difference

141 in the range of the number of OTUs in the mock community samples based on number of cycles

142 and polymerase [Figure 3A]. The closest any of the polymerases came to a total of 8 OTUs, created

143 by running the mock reference 16S sequences through mothur processing, was at 25 and 30 cycles

144 [Figure 3A]. Differences between polymerases for the number of OTUs created were observed

145 as early as 20 cycles in the mock community (F-stat = 15.82, P-value = 0.002) [Table S4]. Using

146 a Tukey post-hoc test, the majority of differences for the number of OTUs detected in the mock

147 community was largely due to Kappa and Platinum versus the other polymerases across the number

148 of cycles used [Table S5].

149 We next investigated the effect polymerases and number of cycles had on the bacterial community

150 composition in more detail by using the Bray-Curtis index. We observed no difference in the bacterial

151 community composition between any measure tested when using the mock community (P-value

152 > 0.05) [Figure 3B]. Finding minimal differences in overall bacterial community composition, we

153 next examined if specific taxa vary depending on polymerase and number of cycles. We found that

154 OTUs that taxonomically classified to *Salmonella*, *Escherichia*, *Enterococcus*, and *Staphylococcus*

155 differed based on polymerase used [Table S6 & S7]. These specific OTUs were all members of

156 the mock community and the differences were most pronounced at 25 and 30 cycles [Table S7].

157 The majority of the differences between taxa were due to differences between a single polymerase

158 (Kappa) and the other polymerases tested [Table S7].

159 Based on these observations, we created Random Forest models to classify samples based

160 on number of cycles or polymerase used. When assessing the Random Forest models there

8

161 was a difference between models built to classify number of cycles versus those built to classify

162 polymerase used [P-value = 5.06e-07]. Although there was a difference, neither model was

163 successful at correctly classifying samples based on 16S rRNA gene sequencing data (cycles

164 model, probability of correct classification = 0.42 (0.4 - 0.43)(min - max) versus polymerase model,

165 probability of correct classification = 0.39 (0.37 - 0.4)). Our observations in mock communities

166 suggest that although differences are detected based on number of cycles or polymerase used, the

167 overall community-wide differences are subtle.

168 ***Few differences based on number of cycles and polymerase used were identified in fecal***

169 ***samples.*** Unlike mock community samples, an overall difference in the number of OTUs was only

170 detected between polymerases at 35 cycles in fecal samples (F-stat > 16.35, P-value = 9.7e-05)

171 [Table S4], and a Tukey post-hoc test failed to identify any differences between specific polymerases

172 used (P-value > 0.05) [Table S5]. However, differences in the range of the number of OTUs detected

173 for fecal samples was dependent on the polymerase used (e.g. Accuprime at 35 cycles = 84 - 106

174 versus Phusion at 35 cycles = 84 - 136) [Figure 4A]. There was also a trend for lower number of

175 cycles (15-20) to result in a reduced range in the number of OTUs versus higher number of cycles

176 (25, 30, and 35) for all polymerases (e.g. Phusion at 15 cycles = 10 - 19 versus Phusion at 35

177 cycles = 84 - 136) [Figure 4A]. Based on these observations, there are only small differences in the

178 total number of OTUs detected in fecal samples that are based on number of cycles or polymerases

179 used.

180 When using the Bray-Curtis index, we observed that the affect polymerases and number of

181 cycles had on the bacterial community composition in fecal samples was minimal. Within each

182 respective 5-cycle increment comparison there was no difference in Bray-Curtis index between

183 the polymerases (P-value > 0.05) [Figure 4B]. When using PERMANOVA to test for community

184 differences based on any of the number of cycles within polymerases, only Phusion had cycle

185 dependent differences (P-value = 0.03). Additionally, Phusion was one of two polymerases that

186 had enough sequences to be rarefied to 1000 sequences at 15 cycles. There was also an overall

187 decrease in Bray-Curtis index by cycle comparison group (e.g. the 15 cycle versus 20 cycle group

188 compared to the 30 cycle versus 35 cycle group) (P-value < 0.01) [Figure 4B]. Using a Dunn's

189 post-hoc test the 15 cycle versus 20 cycle and 20 cycle versus 25 cycle comparison groups had a

9

higher Bray-Curtis index than the 30 cycle versus 35 cycle comparison group (P-value < 0.05). In addition to assessing community composition by Bray-Curtis index, we also investigated differences in OTUs based on polymerase at each number of cycle used and no significant differences could be found (P-value $\geqslant$ 0.01, corrected P-value = 1). Overall, these results suggest that in fecal samples the number of cycles and polymerase used only minimally change the bacterial community composition.

Finally, we built Random Forest models to classify samples for the number of cycles, polymerase used, or individual it was obtained from. Using 16S rRNA gene sequencing data there was a large disparity in the model's ability to correctly classify samples based on polymerase used, number of cycles, and individual (P-value $\leqslant$ 5.49e-07). There was a clear difference in the success of the model used to classify individuals (probability of correct classification = 0.87 (0.86 - 0.9)) versus the models created to classify number of cycles or polymerase (cycles model, probability of correct classification = 0.26 (0.25 - 0.27)(min - max) and polymerase model, probability of correct classification = 0.18 (0.17 - 0.2)). Additionally, the top 10 most important OTUs to the polymerase and number of cycle models were not the most important OTUs to the model that classified individuals [Figure 5]. This suggests that OTUs that change the most due to the number of cycles and polymerase in fecal samples are not the same as OTUs that are part of the biological variation between individuals [Figure 5]. Collectively, our observations show that despite a variety of errors associated with the amplification process, it is still possible to detect the bacterial community variation between individuals.

Discussion

Previous studies have reported GC dependent amplification differences (Polz & Cavanaugh, 1998) and we confirm that these differences still persist in high fidelity DNA polymerase when analyzing mock community samples [Figure 1]. Additionally, these specific polymerases have different sequence error rates and chimera prevalence [Figure 2]. Chimera prevalence in particular was strongly associated with the total number of OTUs detected in a mock community [Figure 2E]. This total number of OTUs also varied by polymerase used for these mock community samples [Figure 3A]. The range in the number of OTUs observed increased with the number of cycles and the change in range was dependent on the polymerase for both mock community and fecal samples [Figure 3]. However, these differences did not translate to large bacterial community composition changes based on polymerase [Figure 4]. Even though there were bacterial community composition changes based on the number of cycles they occurred independently of the polymerase used [Figure 4]. Additionally, there were no OTU-based differences observed within the number of cycles between any of the polymerases for fecal samples. When Random Forest models were created to classify number of cycles, polymerase, and individual based on the 16S rRNA gene sequencing, the model performance for individuals was significantly greater than all other models tested [Figure 5A]. In addition to the better model performance of individuals, the most important OTUs to this model were not the most important OTUs for the other models tested [Figure 5B]. Our observations show that differences between high fidelity DNA polymerases can be found. However, when using 16S rRNA gene sequencing these technical differences are dwarfed by biological differences between fecal bacterial communities within individuals.

The small differences observed due to error rate and chimera prevalence may be due to the actual DNA polymerase family being used within the PCR mix. DNA polymerases from distinct families have different binding affinities and error correction capacity (Ishino & Ishino, 2014). However, based on the observations within our study this is unlikely to be the only contributor. Within our study the highest and lowest chimera prevalence both belonged to a family A polymerase (Platinum and Accuprime[TM] respectively) (Ishino & Ishino, 2014). Additionally, based on the information supplied by the respective manufacturers, the differences between the two PCR mixtures are not immediately

11

apparent. Both PCR mixtures contain a recombinant *Taq* DNA polymerase, a *Pyrococcus* spp GB-D polymerase and a platinum *Taq* antibody. Since it is not possible to know everything about the mixture beyond what was willingly provided by the manufacturer, it is possible that differences in how the recombinant *Taq* was generated or other compounds within the PCR mixture could be a contributing factor for the differences in error rate and chimera prevalence. Beyond the choice of the type of polymerase, there may be other ways to reduce the affect of polymerase dependent error rates and chimera prevalence on the downstream results.

Based on polymerase used, our observations generally found no difference when using the Bray-Curtis index to measure the bacterial community. Specifically, there was no difference in distance between successive 5-cycle increments within samples between the polymerases when using the Bray-Curtis index [Figure 4]. One possible reason for this outcome is that many of the OTUs generated by polymerase dependent error rates and chimera prevalence are likely not highly abundant, allowing the Bray-Curtis index to be able to successfully down-weight these OTUs (Minchin, 1987). The choice of downstream diversity metric could be an important consideration in helping to mitigate some of the observed polymerase dependent differences in error rate and chimera prevalence. Metrics that solely use presence/absence of OTUs (e.g. Jaccard (Real & Vargas, 1996), richness) may be less robust to polymerase dependent error rates and chimera prevalence. When choosing a distance metric, careful consideration of the biases introduced from the PCR step of the 16S rRNA gene sequencing workflow need to be taken into account. One possible way to better choose polymerases may be based on the DNA polymerase family used in the PCR mixture.

Collectively, our data shows that using distinct high fidelity DNA polymerases will result in a different number of OTUs being detected. The differences in the number of OTUs are primarily due to chimera prevalence and sequence error rates that are distinct to the specific polymerase. Despite this variation in the number of OTUs, our Random Forest models were able to correctly classify individuals regardless of the number of cycles and polymerase used. These results suggest that even though there is a large variation in the high fidelity DNA polymerases used across studies, biological variation similar in effect to fecal bacterial community composition differences between individuals will still be consistent.

Conclusion

Although care should always be taken when choosing a polymerase for 16S rRNA gene sequencing, our observations show that the differences between a variety of polymerases are dwarfed by the actual biological variation in fecal communities between individuals. Therefore, if the biological signal of interest is similar to differences in fecal bacterial communities found between individuals, then the type of high fidelity DNA polymerase used will only minimally change the results.

Materials & Methods

Human and mock samples. Fecal samples were obtained from 4 individuals who were part of the Enterics Research Investigational Network (ERIN). The processing and storage of these samples were previously published (Seekatz et al., 2016). Other than confirmation that none of these individuals had a *Clostridium difficle* infection, clinical data and other types of meta data were not utilized or accessed for this study. All samples were extracted using the MOBIO™ PowerMag Microbiome RNA/DNA extraction kit (now Qiagen, MD, USA). The ZymoBIOMICS™ Microbial Community DNA Standard (Zymo, CA, USA) was used for mock communities and was made up of *Pseudomonas aeruginosa*, *Escherichia coli*, *Salmonella enterica*, *Lactobacillus fermentum*, *Enterococcus faecalis*, *Staphylococcus aureus*, *Listeria monocytogenes*, and *Bacillus subtilis* at equal genomic DNA abundance (http://www.zymoresearch.com/microbiomics/microbial-standards/ zymobiomics-microbial-community-standards).

PCR protocol. The five different high fidelity DNA polymerases (hereto referred to as polymerases) that were tested included AccuPrime™ (ThermoFisher, MA, USA), KAPA HIFI (Roche, IN, USA), Phusion (ThermoFisher, MA, USA), Platinum (ThermoFisher, MA, USA), and Q5 (New England Biolabs, MA, USA). The polymerases activation time was 2 minutes, unless a different activation was specified by the manufacturer. The annealing and extension time for Platinum and Accuprime followed a previously published protocol (Kozich et al., 2013) (https://github.com/SchlossLab/MiSeq_ WetLab_SOP/blob/master/MiSeq_WetLab_SOP_v4.md). For Kappa and Q5, the annealing and extension time also were from a previously published protocol (Gohl et al., 2016). For Phusion, the company defined activation and annealing times were used while the extension time followed the Accuprime and Platinum settings.

The number of cycles in the PCR for fecal and mock samples started at 15 and increased by 5 up to 35 cycles, with amplicons used at each 5-step increase for sequencing. The PCR of fecal DNA samples consisted of all 4 samples at 15, 20, 25, 30, and 35 cycles for each polymerase (total sample n=100). The mock communities had 4 replicates at 15, 20, 25, and 35 cycles and 10 replicates for 30 cycles for all polymerases (total samples n=130). No mock community sample had enough PCR product at 15 cycles for adequate 16S rRNA gene sequencing.

14

Sequence processing. The mothur software program was used for all sequence processing steps (Schloss et al., 2009). The protocol has been previously published (Kozich et al., 2013) (https://www.mothur.org/wiki/MiSeq_SOP). Two major differences from the published protocol were the use of VSEARCH instead of UCHIME for chimera detection and the use of the OptiClust algorithm instead of average neighbor for OTU generation at 97% similarity (Edgar et al., 2011; Rognes et al., 2016; Westcott & Schloss, 2017). Sequence error was determined using the 'seq.error' command on mock samples to compare back to the reference 16S sequences of *P. aeruginosa*, *E. coli*, *S. enterica*, *L. fermentum*, *E. faecalis*, *S. aureus*, *L. monocytogenes*, and *B. subtilis* (Schloss et al., 2009; Cole et al., 2013; Rognes et al., 2016). For simplicity, the use of the term 'error' within the context of this study moving forward encompasses changes in the downstream sequencing results due to the amplification step (e.g. higher GC content genomes, base substitutions, deletions, insertions, non-specific amplification, chimeras, etc.).

Analysis workflow. To adjust for unequal sequencing, all samples were rarefied to 1000 sequences for downstream analysis. Analysis of the mock community of each polymerase for GC-based amplification differences, sequence error rate, number of sequences with an error, base substitution, and numbers of chimeras before and after chimera removal with VSEARCH was assessed. Additionally, the correlation between the number of chimeras and the number of OTUs was also assessed. The total number of OTUs, taxa differences, and Bray-Curtis indices were analyzed for both the fecal and mock community samples. Finally, Random Forest models were created to assess whether classification of polymerase, cycles, or individual could be performed best using 16S rRNA gene sequencing data. Additionally, overlap between the most important OTUs to the three models was assessed using mean decrease in accuracy (MDA).

Statistical analysis. All analysis was done with the R (v 3.4.4) software package (R Core Team, 2017). Data transformation and graphing was completed using the tidyverse package (v 1.2.1) and colors selected using the viridis package (v 0.4.1) (Garnier, 2017; Wickham, 2017). High and low GC content was determined based on the median GC percentage of either the V4 region or the whole genome of the bacterial species used in the mock community. Differences in the total number of OTUs were analyzed using an ANOVA with a tukey post-hoc test. For the comparison of the number of OTUS in fecal samples the data was normalized to each individual by cycle

330 number to account for the biological variation. Bray-Curtis distance matrices were generated using

331 mothur. The distance matrix data was analyzed using PERMANOVA with the vegan package (v

332 2.4.5) (Oksanen et al., 2017) and Kruskal-Wallis tests within R. The Random Forest models were

333 run using the caret package (v 6.0.78) (Jed Wing et al., 2017). A total of 100 10-fold CV runs on

334 different 80/20 splits of the data was run to generate a range of the Logloss value. The probability

335 of a correct call was obtained from this Logloss value by taking the negative natural logarithm. For

336 both error and chimera analysis, samples were tested using Kruskal-Wallis with a Dunns post-hoc

337 test. Where applicable, correction for multiple comparison utilized the Benjamini-Hochberg method

338 (Benjamini & Hochberg, 1995).

339 **_Reproducible methods._** The code and analysis can be found here https://github.com/SchlossLab/

Figure 1: Relative abundance differences due to GC is consistent across polymerases. At each number of cycle the points and lines represent the median and with the minimum and maximum relative abundance respectively. Regardless of the number of cycle used a consistent difference between high and low GC bacteria was observed. The dotted line represents the actual relative abundance that each bacterium should be at within the mock community sample.

Figure 2: Error rate and chimera prevalence vary by polymerase and affect the number of observed OTUs. A) The error bars represent the 75% interquartile range of the median error rate. B) Percentage of chimeric sequences without the removal of chimeras with VSEARCH. C) Percentage of chimeric sequences with the removal of chimeras with VSEARCH. D) The total percent of chimeric sequences removed with VSEARCH by cycle number. The error bars represent the 75% interquartile range of the median. E) Chimera prevalence and the the observed number of OTUs are strongly correlated in mock community samples.

Figure 3: The number and range of OTUs in mock and fecal samples varies by polymerase. The points represent the median number of OTUs for the mock samples. The lines represent the range of the minimum and maximum number of OTUs detected within the four fecal samples. The dotted black line represents the number of OTUs detected when only the references sequences for the mock community are clustered. A) The range in the number of OTUs detected in the mock samples increased as cycle number increased. This range was also larger for specific HiFi DNA polymerases. B) The range in the number of OTUs detected in the different fecal samples increased as cycle number increased. This increased range also was larger for specific HiFi DNA polymerases.

Figure 4: Lower five-cycle intervals have larger differences than higher five-cycle intervals using Bray-Curtis. A) Within replicate difference based on the next 5-cycle PCR interval in mock samples. B) Within person differences based on the next 5-cycle PCR interval in fecal samples. The points represent the median Bray-Curtis index for the samples. The lines represent the range of the minimum and maximum Bray-Curtis index value for each PCR 5-cycle increment comparison. The closer a sample is to a Bray-Curtis index of 1.00 the more dissimilar the bacterial community is of the two compared number of cycles.

Figure 5: Biological variation in bacterial community composition due to individual was larger than number of cycles and polymerase used. A) Using 16S rRNA gene sequencing, the classification of individuals was higher than any other model tested. The lines represent the median probability of correct classification and the gray points represent the individual probability from one run out of the 100 10-fold CV runs. B) The most important OTUs to the model classifying individuals are not the same as those that are most important for the number of cycles or polymerase used.

Figure S1: No preference for specific base subsitutions was observed across the polymerases in mock community samples.
